Oral Iron Bioavailability

Iron deficiency is the most common nutritional disorder worldwide and accounts for approximately one half of anemia cases [1,2]. Iron deficiency anemia can result from inadequate iron intake, decreased iron absorption, increased iron demand and increased iron loss [3]. Oral iron therapy is the first line therapy to control iron deficiency but, unfortunately, adherence to oral iron therapy can be a barrier to treatment because of Gastro-Intestinal adverse effects such us epigastric discomfort, nausea, diarrhea and costipation [4,5]. These effects may be reduced when iron is taken with meals, but absorption may decrease by 40% [4,5]. Medication such us PPIs (Proton Pump Inhibitors) and events that induce gastric acid hyposecretion (chronic atrophic gastritis, recent gastrostomy or vagotomy) are associated with reduced absorption of dietary iron and iron tablets [4]. Diagnosis of iron deficiency anemia requires laboratory-confirmed evidence of anemia (Table 1) [5] as well as evidence of low iron stores (Ferritin levels low than 30 ng per ml) [5]. Ferrous Sulphate for oral route is still considered the gold standard for iron deficiency anemia also if a poor domiciliary compliance has been observed because of its gastro-intestinal adverse events. In order to improve patient’s compliance versus oral iron therapy a new and particular source of iron, ferrous bysglcinate chelate, has been developed and used in clinical practice [6-16]. Ferrous bysglcinate chelate consists of one molecule of ferrous iron bound to two molecules of glycine to form two heterocyclic rings (Figure 1) [6].

The absorption of iron from ferrous bisglycinate chelate is regulated through the same physiological mechanisms as other inorganic forms of iron. Following oral administration, ferrous bisglycinate chelate adds to the intestinal intraluminal pool of inorganic, non-haem iron and is absorbed intact into the mucosal cells of the intestine, and is subsequently hydrolysed into its iron and glycine components [6].

The intact absorption of ferrous bisglycinate chelate directly into the mucosal cells of the intestine represents the main differences between this iron source and all the other iron salts making ferrous bisglycinate chelate more available and with less Gastro-Intestinal adverse effects after oral administration.

A lot of clinical trials shown clinical bioequivalence between Ferrous Sulphate at high elemental iron dosage and Ferrous Bisglycinate Chelate at low dosage (ratio 4 to 1) confirming the pharmacokinetic differences between the two sources of iron after oral administration [8-11].

Nevertheless, also Ferrous Bisglycinate Chelate treatment alone results in a number of adverse events that limit, also if at a less extent that Ferrous Sulphate, the patient’s domiciliary compliance to oral iron therapy.

Also the taste of the Ferrous Bisglycinate solution, because of “the iron taste” could represent a limit for patients compliance, especially in infants and in children. In order to ameliorate even more oral Iron bioavailability, tolerability and taste of Ferrous Bisglycinate Chelate a new compound named “FERALGINE®” has been developed.

FERALGINE® is a “co-processed compound” between two well Known substances: Ferrous Bisglycinate Chelate and Alginic Acid, two substances defined like G.R.A.S. (Generally Recognized As Safe) by F.D.A: by using spray drying technologies we have been able to “co-processed” the two substances in a new one patent pending compound with a very attractive and interesting profile.

Spray drying technology, the technology that has been used to develop FERALGINE®, comes of age during World War II, with the sudden need to reduce the transport weight of foods and other materials.

This tecniques enables the transformation of feed from a fluid state into dried particulate form by spraying the feed into a hot drying medium [18,19]. It is a continuous particle processing drying operation. Spray drying process mainly involves five steps 1) Concentration: feedstock is normally concentrated prior to introduction into the spray dryer; 2) Atomization: the atomization stage creates the optimum condition for evaporation to a dried product having the desired characteristic; 3) Droplet-air contact: in the chamber, atomized liquids brought into contact with hot gas, resulting in evaporation of 95% of the water contained in the droplets in a matter of a few minutes; 4) Droplet drying: moisture evaporation takes place in two stages: during the first stage, there is sufficient moisture in the drop to replace the liquid evaporated at the surface and evaporation takes place at a relatively constant rate and the second stage begins when there is no longer enough moisture to maintain saturated conditions at the droplet surface, causing a dried shell to form at the surface. Evaporation then depends on the diffusion of moisture through the shell, which is increasing in thickness; 5) Separation: cyclones, bag filter, and electrostatic precipitators may be used for the final separation stage. Wet Scrubbers are often used to purify and cool air so that it can be released to atmosphere (Figure 2) [18,19].

Spray drying is one of the most exciting technologies for the pharmaceutical industry, being an ideal process where the end-product must comply with precise quality standards regarding particle size distribution, residual moisture content, bulk density and morphology. Alginic Acid salts have usually been used like “gastroprotector” for patients affected by GERD (Gastro Esophageal Reflux Disease), by gastric hyperacidity and by pyrosis [18,19]. By applying Spray Drying technology to a solution of Ferrous Bisglycinate Chelate and Alginic Acid we obtained a “new co-processed compound” in which alginic acid and Ferrous Bisglycinate Chelate are present in 1 to 1 ratio and in which every little particle of the powder has the same morphology and quantity of the two different co-processed substances. In the following picture making by stereomicroscopy Wild Heerbrugg Makroskop M420 linked to an OPTIKAM MICROSCOPY DIGITAL USB CAMERA, we could appreciate the uniformity of the content in the FERALGINE® powder (Figure 3) [20].
The new “Co-processed compound” obtained by spray drying technology, allow to iron powder an increased and uniform superficial area and, consequently, a quick and more extensive iron absorption together with an increase in gastrointestinal protection thanks to the more uniform alginic acid distribution in the FERALGINE® powder. In the same time, the uniform presence of alginic acid in the new co-processed compound obtained by a spray-drying technology, decreased iron taste in the final powder, increasing patient’s (but especially children) compliance to oral iron treatment. Concluding, FERALGINE®, a new patent-pending co-processed compound between Alginic Acid and Ferrous Bisglycinate Chelate, seems to be a new therapeutic option for oral iron therapy thanks to its new pharmacokinetic/pharmacodinamic properties that improve metabolism and taste of the well known Ferrous Bisglycinate Chelate.
